We propose a simple method to characterize the diversity of complexity, that is, the degree of unpredictability in a communication network without using complexity indicators, such as the Kolmogorov complexity (K) and the long-term predictability (LT). We first show that a low diversity of complexity corresponds to a simple network in which each element of the network can be specified using an independent and identically distributed random variable. For a network that is a little more complicated, we apply two commonly used complexity indicators, K and LT, to evaluate the diversity of complexity. We find that both K and LT fail to detect a diversity of complexity in this network. Finally, we evaluate the effect of the noise level on the measure and discuss the relationship between the noise level and the diversity of complexity. Clinical significance and management of perioperative persistent propofol infusion syndrome. Propofol infusion syndrome (PRIS) is a rare but life-threatening complication of propofol infusion. Although past reports have suggested an association between the syndrome and cardiovascular dysfunction, a recent study has implicated excessive phospholipid catabolism in PRIS. The incidence of PRIS is probably underestimated, and there is much debate surrounding the optimal strategy for detecting, managing, and treating this condition. To determine the incidence of PRIS in adults, identify risk factors for developing PRIS in noncritically ill patients, and determine the clinical impact of PRIS on patients and in the health care system. A retrospective study was performed at a tertiary care center from January 1998 to January 2004. The perioperative cardiovascular and metabolic profiles of 600 patients were analyzed to determine the incidence of PRIS. In addition, the impact
